0.1 Problem Formulation

The motion of the vehicle i for i = 1, ..., N is governed by the usual longitudinal dynamics model

$$\begin{cases}
\dot{p}_i = v_i, \\
M\dot{v}_i = F_{mot_i} - c_2 - c_3 v_i^2 - Mg \sin(\alpha_i),
\end{cases}$$
(1)

where M is the total mass of the vehicle, α is the road slope, g is the gravitational acceleration, F_{mot} represents the traction force generated by the electric motor, and c_2 , c_3 are parameters to be identified.

The torque is assumed to be proportional to the armature current, I_a and - because of the fixed-gear arrangement - the same is true for the traction force generated by the motor at the wheels:

$$F_{mot_i} = c_1 I_{a_i}. (2)$$

The battery current I_{b_i} is defined as

$$I_{b_i} = \gamma I_{a_i},\tag{3}$$

where γ is the conversion rate. The net electrochemical power (i.e. the one that corresponds to the actual battery charge or discharge) is given by

$$P_{b_i} = I_{b_i} E, \tag{4}$$

where voltage source E is assumed to be constant. Define

$$\dot{x} = \begin{bmatrix} x_{1_i} \\ x_{2_i} \end{bmatrix} = \begin{bmatrix} p_i \\ v_i \end{bmatrix}. \tag{5}$$

Then we can write (1) - (3) into the following state-space form:

$$\begin{cases} \dot{x}_{1_i} = x_{2_i}, \\ \dot{x}_{2_i} = -\frac{c_3}{M} x_{2_i}^2 + \frac{c_1}{M\gamma} I_{b_i} - \frac{c_2}{M} - g \sin \alpha_i. \end{cases}$$
 (6)

It is worthy to mention that the real input is the motor torque, while the design is to control the derivative of the current. Once we have I_{b_i} , the motor torque can be calculated using following equation:

$$T_{mot_i} = \frac{c_1}{\gamma} I_{b_i} r_w,$$

where r_w is the wheel radius.

0.2 Path Planning

Here we use a digraph $\mathcal{G}(\mathcal{V}, \mathcal{E})$ to describe the map, where the elements in the vertex set $\mathcal{V} = \{\nu_1, \dots, \nu_N\}$ represent intersections that the electric vehicle may pass through in the journey, the elements in the edge set

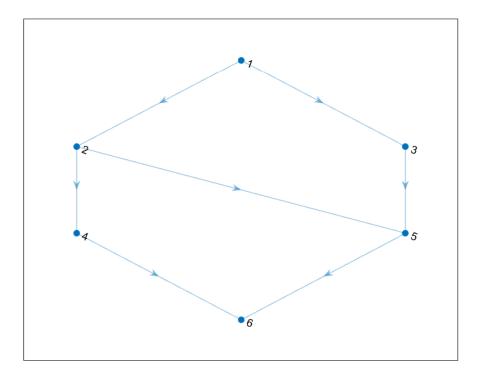

Figure 1: The map.

denote the road segment between two distinct intersections. Without loss of generality, we use ν_1 and ν_N to denote the origin and destination, respectively. An ordered pair (ν_i, ν_j) belonging to the edge set \mathcal{E} means that the electric vehicle can move from intersection ν_i to intersection ν_j . For any $\nu_i \in \mathcal{V}/\{\nu_1, \nu_N\}$, we can always find a sequences of edges starting with ν_1 ending with ν_i and a sequences of edges starting with ν_i ending with ν_N . In other words, our modeling does not include intersections that cannot be reached from the origin or cannot reach the destination. The map used in this homework is generated by the following Matlab code:

and shown in Fig. 1. The

We use \bar{v}_{ij} and l_{ij} to represent the maximum velocity limitation and the length of segment (ν_i, ν_j) , respectively. To simplify the problem, we assume that the electric vehicle keeps the maximum velocity \bar{v}_{ij} when it moves on the segment (ν_i, ν_j) and the road slop of the segment (ν_i, ν_j) is α_{ij} . Thus the energy required to complete (ν_i, ν_j) can be calculated as

$$w_{ij} = EI_{ij}t_{ij}, (7)$$

where $t_{ij} = \frac{l_{ij}}{\bar{v}_{ij}}$ and $I_{ij} = \frac{c_3 \gamma}{c_1} \bar{v}_{ij}^2 + \frac{c_2 \gamma}{c_1} + g \gamma \sin(\alpha_{ij})$. In the dynamic programming scheme, w_{ij} is regarded as the reward of (ν_i, ν_j) , which can be calculated using the following Matlab function:

```
function reward = ppReward(vmax,l,alpha,m,Voc,cl,gamma,Crr, Af, Cd, g, rho)
3 frr = Crr * m * g * \cos(alpha);
                                           % rolling resistance
4 fad = 0.5 * \text{rho} * \text{Af} * \text{Cd} * \text{vmax}^2; % air resistance
  fgx = m * g * sin(alpha);
                                           % grade resistance
6 	ext{ ft = frr + fad + fgx;}
                                           % traction force
                       % armature current
  Ia = ft / c1;
  Ib = gamma * Ia;
                       % battery current
9
11 tf = 1 / vmax;
                      % This is length "l", not number 1.
12 reward = Voc * Ib * tf;
```

The length, maximum velocity, and slope of each segment (ν_i, ν_j) is generated randomly using the following Matlag code:

```
numInter = size(I,1);
2 numEdge = size(I,2);
s = [v0, \neg, \neg] = converterMPH(70);
                                                  % average velocity limitation: 70mph
4 rng(1)
5 vmax = v0 * (1 + rand(numEdge, 1));
                                            % generate maximum velocity for each
                                            % road segment.
  len0 = 10 * 1000;
                                          % average road length: 1km
  len = len0 * (1 + rand(numEdge, 1));
                                           % generate road lenth for each
                                            % road segment.
  alpha = zeros(1, numEdge);
10
11
12 roads = [];
  for i=1:numEdge
      roads = [roads road(len(i), vmax(i), alpha(i))];
14
```

where road is a class defined as

```
1 classdef road
2
       properties
3
                        % the length of the road
           length
4
           velocity
                        % maximum allowable velocity on this road
           slope
                         % road slope
6
7
8
       methods
9
           function obj = road(len, vmax, alpha)
10
               if nargin < 3, alpha = ""; end
11
                if nargin < 2, vmax = ""; end
12
               if nargin < 1, len = ""; end
13
               obj.length = double(len);
14
               obj.velocity = double(vmax);
15
               obj.slope = double(alpha);
16
17
18
19
           function obj= set.length(obj,len)
20
               obj.length = double(len);
21
           function obj= set.velocity(obj, vmax)
22
```

converterMPH is a converter:

```
1 function [mps kph fps] = converterMPH(MPH)
2 % Convert mph to m/s.
3
4 kph = 1.609344 * MPH;
5 mps = 0.44704 * MPH;
6 fps = 1.46666667 * MPH;
7 end
```

Our aim is to find an optimal route starting with ν_1 end with ν_N to minimize the total reward. To achieve this goal, we write the following Matlab function

```
function [path, cost] = ppDP(rewards, I, state, final state)
   if state == finalstate
2
       path = [finalstate];
3
       cost = 0;
4
   else
       fromk = find(I(state,:)==-1);
                                          % Find paths starting with intersection state
6
       num_fromk = size(fromk,2);
                                          % number of paths starting with intersection k
       temp_reward = rewards(fromk);
       temp_cost = zeros(1, num_fromk);
10
       temp_nstate = zeros(1, num_fromk);
       for i = 1:num_fromk
11
12
           temp_nstate(i) = find(I(:, fromk(i)) == 1);
            [¬, cc] = ppDP(rewards, I, temp_nstate(i), finalstate);
13
           temp_cost(i) = cc + temp_reward(i);
14
       end
15
       [MM, II] = min(temp_cost);
16
       cost = MM;
17
       [pp, ¬] = ppDP(rewards, I, temp_nstate(II), finalstate);
18
       path = [state pp];
20
   end
   end
21
```

Meanwhile, we also write a traditional recursive algorithm to verify the correctness of our dynamic programming function:

```
function [path, cost] = ppR(rewards, I, state)
  if state == 1
      path = [1];
3
4
      cost = 0;
  else
5
      tok = find(I(state,:)==1);
                              % Find paths ending with intersection k
6
      temp_reward = rewards(tok);
      temp_cost = zeros(1, num_tok);
10
      temp_pstate = zeros(1, num_tok);
      for i = 1:num_tok
11
         temp_pstate(i) = find(I(:,tok(i))==-1);
         [¬, cc] = ppR(rewards, I, temp_pstate(i));
13
```

```
14          temp_cost(i) = cc + temp_reward(i);
15          end
16          [MM, II] = min(temp_cost);
17          cost = MM;
18          [pp, ¬] = ppR(rewards, I, temp_pstate(II));
19          path = [pp state];
20     end
21     end
```

Now we can get the optimal path using the following parameter setting and code:

```
% Electric Vehicle
               % Total mass of the vehicle: 2300kg
  m = 2300;
                    % Open circuit voltage: 340v
   Voc = 340;
  Crr = 0.01;
                   % Rolling resistance coefficient
  g = 9.8;
                  % Gravitational acceleration: 9.8m/s
  c2 = Crr * m * g * cos(0);
                                  % Rolling resistance
  rho = 1.23;
                                  % Air density
   Af = 2.1;
                                  % Vehicle frontal area: 2.1m^2
  Cd = 0.38;
                                  % Aerodynamic drag coefficient
  c3 = 0.5 * rho * Af * Cd;
10
  gamma = 1.2;
                                  % The conversion rate: Ib = gamma*Ia
                                  % The ratio between Fmot and Ia: Fmot = c1 * Ia
12 	 c1 = 30;
13
   rewards = [];
14
   for ii=1:numEdge
15
       rewards = [rewards ppReward(roads(i).velocity,roads(i).length,...
           roads(i).slope, m, Voc, c1, gamma, Crr, Af, Cd, g, rho)];
17
18
19
   [pathR, costR] = ppR(rewards, I, numInter);
20
21
   [path, cost] = ppDP(rewards, I, 1, numInter);
```

The results of ppR(rewards, I, numInter) and ppDP(rewards, I, 1, numInter) are same, which are

```
1 pathR =
2
3     1     2     4     6
4
5 path =
6
7     1     2     4     6
```

0.3 Car-following Model

Now we consider a platoon with 4 electric vehicles, which can be defined using a new class EV:

```
t
11
12
            dt
            tf
13
            alpha
14
15
            vDes
16
            aMax
17
            bMax
18
            bnHat
19
20
            Ln
21
                     % Mass
                     % Length
            1
23
24
            c1;
25
            c2;
26
            c3;
27
28
                     % [X, dX]
29
            Х
                     % position vector [X]
30
                    % velocity vector [dX]
31
32
33
            dx
34
                      % Control Input [Ib]
35
            u
              Ib
                         % Battery current
36
37
        end
38
39
        properties
           r_des
40
            r_err
41

If EV i is the leader vehicle, its desired velocity is the maximum velocity limitation of each segments. Otherwise, its desired velocity can be calculated through Gipps' model:

```
1 function [v,v1,v2] = gipps(dt,v_,aMax,vDes,bMax,xn_,x_,Ln,vn_,bnHat)
2 % The Gipps Model
_{\rm 3} % This function is based on Eq. (2.12) in elefteriadou14
  % v is the speed of vehicle n+1 at time t+Delta_t
  % dt is the apparent reation time, a constant for all vehicles
  % v_ is the speed of vehicle n+1 at time t
  % aMax is the maximum acceleration which the driver of vehicle n+1 whishes
          whishes to undertake
  % vDes is the speed at which the driver of vehicle n+1 whishes to travel
  % \, \mathrm{bMax} is the actual most severe deceleration rate that the driver of
         vehicle n+1 wishes to undertake (b(n+1)<0)
  % xn_ is the location of the front of vehicle n at time t
   % x_{i} is the location of the front of vehicle n+1 at time t
13
  % Ln is the effective size of vehicle n; that is the physical length plus
        a margin into which the following vehicle is not willing to introduce
15
  응
        even at rest
  % vn_ is the speed of vehicle n at time t
17
   % bnHat is the most severe deceleration rate that vehicle n+1 estimates for
18
19
           vehicle n
20
v1 = v_ + 2.5*aMax*dt*(1 - v_/vDes)*sqrt(0.025 + v_/vDes);
22 v2 = bMax*dt + sqrt(bMax^2*dt^2 - bMax*(2*(xn_ - Ln - x_)-v_*dt-vn_^2/bnHat));
   v = \min([v1, v2]);
24
  end
```

The controller we used is a simple proportional controller. We set P=3 for the leader vehicle and P=100 for the follower vehicle:

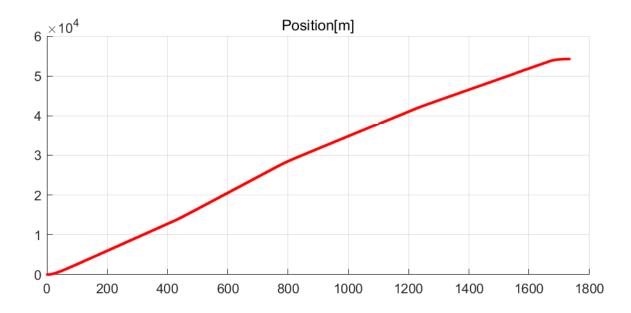

```
6
   I_{n} = 7.62:
         the effective size of vehicle n; that is the physical length plus
         a margin into which the following vehicle is not willing to introduce
9
10
         even at rest
11
   ev2\_initStates = [-Ln, ...
                                            % position
12
       0]';
                                            % velocity
13
14
   ev3_initStates = [-2*Ln, ...
                                              % position
                                            % velocity
15
       0]';
   ev4_initStates = [-3*Ln,...
                                              % position
16
17
       01';
18
   ev1_initInputs = [0];
19
20
   ev1_gains = containers.Map({'P_r','I_r','D_r', ...

42
       simulationTime, dt, alpha, Ln);
43
```

Results are shown in Fig. 2 and Fig. 3. Fig. 2 shows the position and velocity of the leader vehicle. From this figure, we can see that the leader vehicle passes 3 intersections before it reaches the destination. On each segment between two distinct intersections, its velocity tracks the maximum allowable velocity of the road. Fig. 3 shows the spacing and velocity difference between the leader vehicle and each follower vehicle. In this figure, the vehicles achieve the platoon behavior: they try to keep a safe inter-vehicles distance and the same velocity. From the sub-figure titled spacing, we can also find that the vehicles will keep a longer spacing to keep traffic safe if their velocity increase.
